Abstract

Changes in forest cover cause changes in streamflow, however this change is different between deforestation and reforestation, and strongly affected by climate, with drier climates indicating larger changes in streamflow. Deforestation causes a 32% greater change in flow compared to reforestation. Area of the catchment only affects the change in streamflow after log transformation, given the wide variety in the data from small scale paired watershed studies. Smaller studies dominate the database with 42% of the data < 1 km2 and 65% of the data < 10 km2. Length of the study and initial year of the study did not affect the change in flow, in contrast to other reported studies. Despite these findings, overall explained variance (38%) is low due the quality of the inputs and additional unknown confounding factors. Three recent papers review and analyse large global datasets related to impacts of forest cover on streamflow. Using three different approaches, they all find a strong relationship between forestation/deforestation and streamflow. However, the past approaches in the literature are variable and can be substantially improved in statistical rigour, and indicate different confounding factors on the impact of forestation. The data for these three papers were reviewed, combined and re-analysed to answer the following new and older questions: 1) How is streamflow impacted by the change in forest cover as a function of catchment area; 2) how is this relationship conditioned by the length of the study, and climate; and 3) are there other possible variables that impact the observed change in streamflow? Generalised additive models were used to run flexible regressions including multiple variables.

1. Introduction

There has been an long and on-going discussion in the hydrological literature around the impact of forests on streamflow (Andréassian, 2004; Brown et al., 2013, 2005; Filoso et al., 2017; Jackson et al., 2005; Zhang et al., 2017). The historic work highlights a general consensus that if forest areas increase, streamflow decreases and vice-versa. The most dramatic result in relation to this, is

Figure 5 in Zhang et al. (2011) indicating (for Australian catchments) a 100% decrease in streamflow for catchments with 100% forest cover. However, on the other end of the spectrum, for three French catchments (Cosandey et al., 2005), there was no change in streamflow characteristics in two of the catchments after deforestation.

For the purpose of this paper, *watershed* and *catchment* are interchangeable terms. Many of the US studies use *watershed*, while European and Australian studies use *catchment*. In particular, we retained the term "paired watershed studies" as this is the most common terminology, but further mostly use the term catchment.

Several review papers have summarized the plethora of forestation and deforestation studies across the globe, in relation to paired watershed studies (Bosch and Hewlett, 1982; Brown et al., 2005), related to reforestation in particular (Filoso et al., 2017), and more generally (Jackson et al., 2005; Zhang et al., 2017). These studies aim to generalize the individual findings and to identify if there are global trends or relationships that can be developed. The most recent reviews (Filoso et al., 2017; Zhang et al., 2017) developed an impressive global database of catchment studies in relation to changes in streamflow due to changes in forest cover. The Zhang et al. (2017) dataset, which covers over 312 studies, is described in terms of the change in streamflow as a result of the change in forest cover, where studies related to both forestation (increase in forest cover) and deforestation (decrease in forest cover) were included. In contrast, the paper by Filoso et al. (2017) focused primarily on reforestation, and covered an equally impressive database of 167 studies using a systematic review. In this case the collected data is mostly coded as count data and only a subset of 37 studies was analysed for actual water yield change. There is some overlap between the two data sets, but there are also some studies unique to both sets.

The conclusions of the first paper (Zhang et al., 2017) suggest that there is a distinct difference in the change in flow as a result of forestation or deforestation between small watersheds (catchments), defined as < 1000 km^2 and large watersheds (catchments) > 1000 km^2. While for small catchments there was no real change in runoff with changes in cover, for large catchments there was a clear trend showing a decrease in runoff with and increase in forest cover. Their main conclusion was that the response in annual runoff to forest cover was scale dependent and appeared to be more sensitive to forest cover change in water limited catchments relative to energy limited catchments (Zhang et al., 2017).

The second study (Filoso et al., 2017) was a systematic review which classified the historical research and highlighted gaps in the spatial distribution, the types of studies and the types of analysis. Their main conclusion was also that reforestation decreases streamflow, but that there were many interacting factors. For a subset of quantitative data (37) they showed a log-linear relationship between decreasing catchment size and an increasing decline in streamflow. In addition, they identified that studies with shorter periods of data collection resulted in larger declines in streamflow.

A final summary paper that includes much of the same data as Zhang et al. (2017) and Filoso et al. (2017) is Zhou et al. (2015), which has one author in common with Zhang et al. (2017). However, this paper aims to explain the variation in the data using the Fuh model, and in particular aims to link the variation in the observed data to variations in the exponent m in the model. A key observation is that in drier environments, the effects of deforestation are much greater than in wetter environments, which is also suggested by Figure 4 in Zhang et al. (2017).

Encouraged by the work presented by Zhang et al. (2017), Filoso et al. (2017) and Zhou et al. (2015) and the large database of studies presented by these authors, we believe more can be done to add to this important discussion. In this paper, the aim extend the analysis of the collected data and to expand and combine the data sets.

In particular, the main method in the work by Zhang et al. (2017) is a single covariate linear regression, and in Filoso et al. (2017) the focus is mainly on classification and there is again some single covariate linear regression. As Zhang et al. (2017) points out, a main assumption in their work is that the catchment size threshold at 1000 km^2 is a distinct separation between "small" and "large" catchments. However, the subset of 37 data points in Filoso et al. (2017) (their Figure 9) does not appear to support this, suggesting a continuum. And while the work Filoso et al. (2017) provides important insights in study types, analysis types, forest types and broad classification, there is limited quantification of actual impact, and focussed only on forest cover increase and did not deal with forest cover removal.

As a result the objective of this paper is to 1) enhance the data set from Zhang et al. (2017) with further catchments (such as from Filoso et al. (2017)) and spatial coordinates and 2) to analyse the possibility of non-linear and confounding partial effects of the different factors and variables in the data using generalised linear (GLM) and generalised additive models (GAM Wood (2006)).

Building on the analyses by Zhang et al. (2017) and Filoso et al. (2017), and combining their conclusions, the main hypothesis to test is that the change in streamflow is impacted by the change in forest cover. However, this change is is potentially modulated by the area under consideration (affecting the length of the flowpaths Zhou et al. (2015)), the length of the study (c.f. Jackson et al. (2005); Filoso et al. (2017)) and the climate (as indicated by either E0/Pa or latitude and longitude Filoso et al. (2017); Zhou et al. (2015)).

However, there could be further confounding factors, which are eluded to by Filoso et al. (2017):

- the type of analysis, i.e. paired watershed studies, modelling, time series analysis etc.

- the age of the study, assuming that historical studies might not have had the ability to measure at the accuracy that currently is available to researchers, or that more careful historical attention to detail in field studies might have been lost more recently due to reductions in research investment.

Finally, this work aims to point to further research that can expand this area of work, based on the collected data, to better understand the impact of forest cover change on streamflow.

2. Methods

2.1. The original data sets

The starting point of this paper is the data base of studies which were included in Zhang et al. (2017) as supplementary material. The columns in this data set are the catchment number, the catchment name, the Area in km^2, the annual average precipitation (Pa) in mm, the forest type, hydrological regime, and climate type, the change in forest cover in % ($\Delta F\%$) and the change in streamflow in % ($\Delta Qf\%$), based on equation 1 in Zhang et al. (2017)), the precipitation data type, the assessment technique, and the source of the info, which is a citation. Several of these columns contain abbreviations to describe the different variables, which are summarised in Table 1.

Table 1 Summary of abbreviations of factors used in the Zhang et al. (2017) data set

Factor	Abbreviation	Definition
forest type	CF	coniferous forest
	BF	broadleaf forest
	MF	mixed forest
hydrological regime	RD	rain dominated
	SD	snow dominated
climate type	EL	energy limited
	WL	water limited
	EQ	equitant
precipitation data type	OB	observed
	SG	spatial gridded
	MD	modelled
assessment technique	PWE	paired watershed experiment
	QPW	quasi-paired watershed experiment
	HM	hydrological modelling
	EA	elastictity analysis
	SH	combined use of statistical methods and hydrographs

While Zhang et al. (2017) use the dryness index in their analysis, and calculate the variable climate type from this index, the potential or reference evapotranspiration was not originally included as part of the published data set. In this paper, we used only the dryness index and did not use the climate type as a variable (as they are interchangeable). We combined the tables for small catchments (< 1000 km^2) and large catchments ($>= 1000$ km^2) in our analysis.

2.2. Additional data collection

To enhance the existing data set, this study added additional variables and cross-checked the studies with the data set from Filoso et al. (2017). In particular, we focussed on the 37 data points included in the quantitative analysis in Filoso et al. (2017).

In addition, additional variables added were the latitude and longitude for the center of the catchment as an approximation of its spatial location. Using this information reference evapotranspiration (E_0) was extracted from the Global Aridity Index and Potential Evapo-Transpiration (ET_0) Climate Databasev2 (Trabucco and Zomer, 2018), if a value of E_0 was not available from the original papers. For large catchments, this value, similar to annual average rainfall, is only an approximation of the climate at the location.

Similar to Zhang et al. (2017), the "dryness index" was calculated from the reference evapotranspiration and the annual average rainfall (Pa) as:

$$D = \frac{E_0}{Pa} \tag{1}$$

The length of the study can be a variable influencing the change in flow (Filoso et al., 2017; e.g. Jackson et al., 2005), as for example, more mature plantations are thought to have smaller impacts on flow or regrowth might follow a "Kuczera curve" (Kuczera, 1987). Therefore, the length of the study calculate as the difference between the starting data and completion date of the different studies was extracted from the references provided by Zhang et al. (2017). The length of the study was already included in the data from Filoso et al. (2017), but these were checked against the original publications.

Several additional data points from catchment studies were extracted from Zhang et al. (2011), Zhao et al. (2010), Borg et al. (1988), Thornton et al. (2007), Zhou et al. (2010), Rodriguez et al. (2010), Ruprecht et al. (1991) and Peña-Arancibia et al. (2012), and these were checked against the existing studies to prevent overlap. In the citation column in the data set, in general the main reference for the calculated change in streamflow was used, because sometimes the original study did not provide the quantification of the change in streamflow (i.e. Table 6 in Zhang et al. (2011)). We also removed one data point from the analysis, which corresponds to catchment #1 (Amazon) in Zhang et al. (2017). This is because the cited reference (Roche, 1981) only relates to 1 and 1.5 ha paired catchment studies in French Guyana, and in which the actual change in forest cover is not recorded. Furthermore, the change in flow for catchment #76 was corrected from 600% to 157% after review of the original publication (Baker Jr., 1984). Finally, on review of all the data in Zhang et al. (2017) and Filoso et al. (2017), 29 potential duplicates were identified and flagged in the data.

The final column in the improved data set is a "notes" column, which is not further used in the analysis, but gives context to some of the data for future research and highlights some of the discrepancies that we found between the original papers and the data in the tables from Zhang et al. (2017).

2.3. Statistical modelling

To estimate how the change in streamflow is affected by the change in forest cover while considering the effects of the other variables, we applied generalised additive modelling (GAM) (Wood, 2006).

The general model tested is:

$$\Delta Qf\% \sim \Delta\% forest\ cover_{positive} + sign_{forest\ cover} + \sum X_i + \sum s(Z_i) + \varepsilon \quad (2)$$

Here X_i are factorial variables, while Z_i are continuous variables. The model assumes no direct interactions and all variables are additive. The changes in forest cover contain both positive (forestation) and negative values (deforestation). In Zhang et al. (2017), these changes were jointly analysed, assuming the effect on the change in flow was linear and the effect if removing forest cover was the same as an equivalent reforestation. However, the impact of an increase in forest cover can be different from the same fractional decrease in forest cover. Therefore all the change in forest cover data is converted to positive values, and an additional column ($sign_{forestcover}$) is added that indicates whether it was a forest cover increase or decrease. A further assumption in the model is that all continuous variables Z_i (such as annual precipitation (Pa)) can have a linear or non-linear relationship with $\Delta Qf\%$. This means that a smooth function $s()$ is applied to the Z_i variables. For the smoothing function we applied thin plate regression splines with an additional shrinkage penalty which means the terms can be shrunk to 0 if not significant (Wood, 2006).

For the model in equation 2, we initially only used the data from Zhang et al. (2017) to make sure that the additional catchments added to the data set did not influence the results. Subsequently the analysis was repeated and the additionally identified catchments were added.

More generally the results were analysed to identify:

1. the significance of the different variables
2. the direction of the categorical or shape of the smooth variables

3. Results

3.1. Description of the data

The overall dataset contains 330 observations of changes in flow, which includes the newly identified data sets and after removing identified duplicate data and lines with missing data. In contrast, the original dataset from Zhang et al. (2017) contained 312 catchments and the Filoso et al. (2017) study used 37 catchments (Table S2 in Filoso et al. (2017)). The overall distribution of changes in flow is highly skewed as is the distribution of changes in forest cover and Area. The values of changes in flow greater than 100% and smaller than -100% clearly create long tails on the change in flow distribution. Note also the large number of studies with 100% forest cover reduction. Smaller catchments

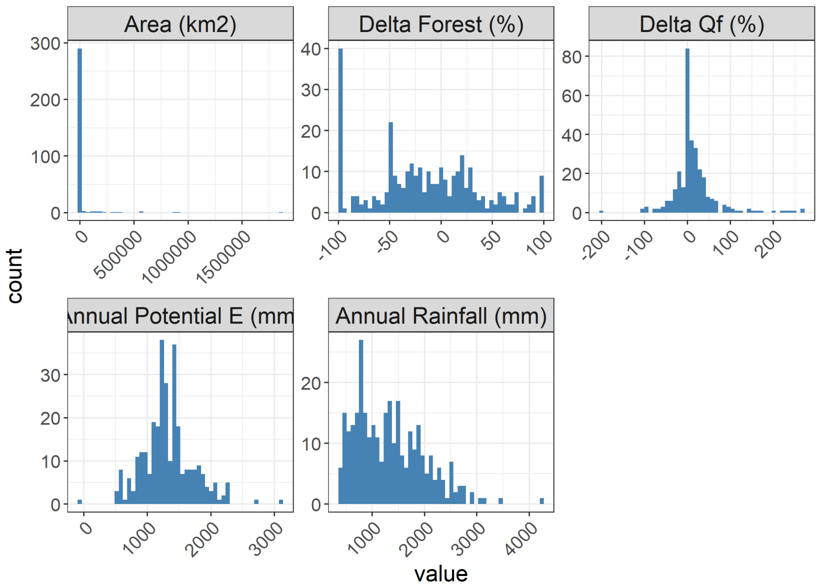

Figure 1: Overview of the distribution of the data set for five of the included variables.

dominate the database with 42% of the data from catchments < 1 km^2 and 65% of the data for catchments < 10 km^2 (Figure 1).

In addition, this shows that for the data related to forest decreases, there is almost always a positive flow change (Figure 2). In other words, flow almost always increased. However, for increases in forest cover, this is not the case, and flow can both increase and decrease. However in both cases the variability in the reported change in flow increases with the increase in forest cover change.

3.2. The general relationship between change in forest cover and streamflow

Following Zhang et al. (2017), the first step is to investigate the percent change in flow as a linear effect of the percent change forestry and modulated by the direction of the change, either an increase in forest cover, or decrease in forest cover:

$$\Delta Qf\% \sim \ \Delta\% forest\ cover_{positive} + sign_{forest\ cover} + \varepsilon \tag{3}$$

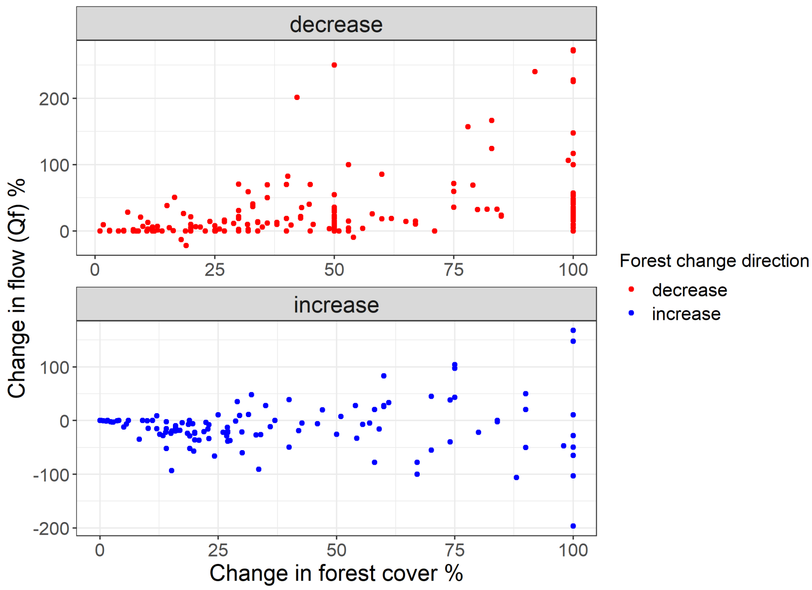

Figure 2: Changes in flow as a function of increases and decreases in forest cover

Table 2: Summary results of the first regression model predicting change in streamflow from change in forest cover and accounting for the direction of the change. The first three rows relate to the model using the original data base from Zhang et al. (2017). The bottom three rows are the results of the model including the new data.

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	8.65	5.56	1.56	0.12
DeltaF__perc__pos	0.45	0.09	5.26	0
Forest__Signincrease	-29.17	5.79	-5.04	0
(Intercept)	10.76	5.34	2.02	0.04
DeltaF__perc__pos	0.41	0.08	5.04	0
Forest__Signincrease	-38.03	5.26	-7.23	0

The overall variance explained in this model (equation (3)) is not high with an adjusted r^2 of 0.23, it generally supports the hypothesized relationship between the change in forest cover and the change in flow. The model suggests that for every 1% change in forest cover, on the average, the flow changes 0.45%. However the change in flow is different for forest cover decreases compared to forest cover increases. In fact, forest cover increases decrease flow by 29% less than a similar decrease in forest cover causes flow to increase. So roughly speaking, a 1% forest cover increase on the average decreases flow by $(1-0.29)*0.45\%$,

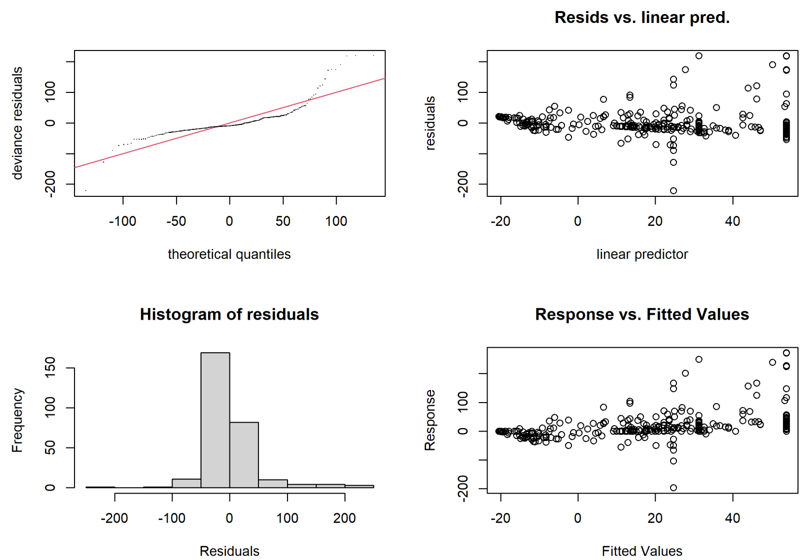

Figure 3: Residual plots for the first simple regression model indicating a slightly fat-tailed residual distribution

while a the percentage forest cover decrease will increase flow by 0.45%.

Of importance here is to highlight the residuals of this regression (equation (3) and Figure 3). These are approximately normal, although there is still significant skew on the upper and lower parts of the distribution (Figure 3). In other words, the distribution of the residuals is somewhat fat-tailed. We will discuss this later.

Including the data from some of the newly identified studies indicates that this mainly strengthens the difference between the forest cover increases and decreases (Table 2), and the result indicate a reduction in the mean decrease in flow as a result of forest cover change if the new data is included.

It is however it is clear from the lack of explaining power for the model, that there could be confounding factors, as alluded to in the methods. The obvious ones being catchment dryness and area (following Zhang et al. (2017)), which we will analyse later.

3.3. The effect of location on the globe

As indicated, an initial hypothesis relates to whether there is a strong spatial global gradient as captured by latitude and longitude. These data were added for the different studies, mostly by using the data reported by the authors, but in some cases approximating the location of the centre of the catchment using Google Maps. In the dataset, an additional column is added to indicate the source of the location data. As the global map (Figure 4) shows, the distribution of case study catchments covers multiple continents and shows some distinct

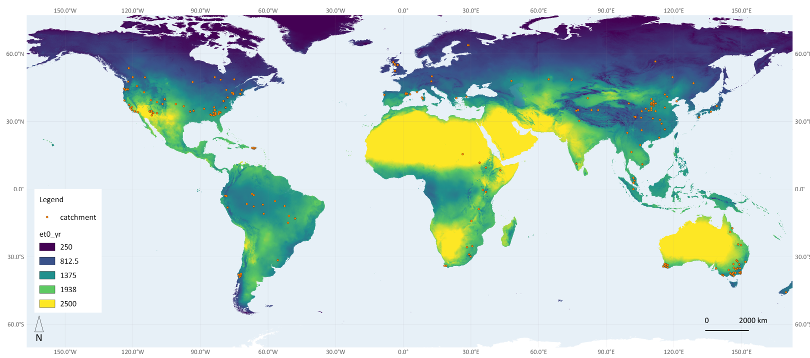

Figure 4: Distribution of included catchments across the globe based on reported or estimated latitude and longitude

clustering in parts of the world. Of interest is whether the spatial clustering also indicates a difference in response to forest cover change:

$$\begin{aligned}\Delta Qf\% \sim\ & \Delta\% forest\ cover_{positive} + sign_{forest\ cover} + \\ & Latitude + Longitude + \varepsilon\end{aligned} \tag{4}$$

Table 3: Results of the model including Latitude and Longitude including new data

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	10.99	5.75	1.91	0.06
DeltaF_perc_pos	0.42	0.08	5.13	0
Forest_Signincrease	-38.99	5.54	-7.04	0
Latitude	-0.01	0.09	-0.13	0.9
Longitude	0.01	0.03	0.26	0.79

There appears to be no significant gradient in either latitude or longitude (Table 3), suggesting that the distribution of the catchments across the globe has little influence on the overall result. The total explaining power of the model is still low with an adjusted r^2 of 0.23 suggesting further factors influencing the change in streamflow that are currently not included in the model.

3.4. Impact of climate

Climate, and in particular evapotranspiration can have a significant effect on the streamflow change as represented by the dryness index, which is also highlighted by both Zhang et al. (2017) and Jackson et al. (2005). Increased evapotranspiration could lead to drier catchments, unless balanced by rainfall (such as possibly in the tropics). Initially, we tested models using annual average precipitation (*Pa (mm)*), but because of the interactions between precipitation, evapotranspiraton and the dryness index, we concentrated on the dryness index as the key variable. Given that Latitude and Longitude were not significant, we dropped these from the model.

$$\begin{aligned}\Delta Qf\% \sim\ & \Delta\% forest\ cover_{positive} + sign_{forest\ cover} + \\ & Dryness + \varepsilon \end{aligned} \tag{5}$$

Table 4: Results of the model including the dryness index «««< HEAD

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	8.83	6.3	1.4	0.16
DeltaF__perc__pos	0.4	0.08	4.88	0
Forest__Signincrease	-38.26	5.32	-7.19	0
Dryness	1.7	2.67	0.64	0.52

4. The results from this model (equation (5) **and Table 4) interestingly indicate no impact of dryness modulating the change in streamflow as a function of the change in forest cover change, which is surprising in light of earlier reported results (Filoso et al., 2017; Zhang et al., 2017). In this case, the evidence is highly doubtful (p = 0.52). However, it is very well possible that there is a further interaction in the data with other variables or unknown variables that this simpler version of the model cannot identify. This is partly evidenced by the fact that the overall variance explained is still low, with an adjusted r^2 of 0.22.**

The results from this model (equation (5) and Table 4) confirm that dryness is a clear confounding factor related to the change in streamflow as a function of the change in forest cover change. In this case the evidence is not very strong (p = 0.52. However, if the dryness index doubles (remembering that Dryness = 1 when E0 = Pa, so in this case E0 = 2×Pa, which is very dry), the change in runoff is ~6% greater. Again, overall variance explained is not very much, with an adjusted r^2 of 0.22. »»»> 70692a2b708e51dd658780f5487e0fb00aaf13a7

Table 5: catchments for which the dryness index > 4

«««< HEAD There are also possible issues with the data, as a few of the catchments have Dryness values that are very large (> 4) and these values have high leverage in the data, affecting the residual distribution. These catchments are listed in Table 5. ======= There possible issues with the data, a few of the catchments have Dryness values that are very large (> 4) and these values have high leverage in the data, affecting the residual distribution. These catchments are listed in Table 5. »»»> 70692a2b708e51dd658780f5487e0fb00aaf13a7

4.1. Is there a distinct effect of area?

The major hypothesis to test is the effect of area on the change in flow, following the analysis by Zhang et al. (2017) and Filoso et al. (2017). Given the highly skewed distribution of the catchment areas (Figure 1), a log base 10 transformation was applied to the variable *Area (km^2)*.

$$\begin{aligned} \Delta Qf\% \sim\ & \Delta\% forest\ cover_{positive} + sign_{forest\ cover} + \\ & log10(Area\ (km^2)) + Dryness + \varepsilon \end{aligned} \tag{6}$$

Table 6: Results of the model including Area and the dryness index

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	15.37	7.24	2.12	0.03
DeltaF__perc__pos	0.3	0.1	2.94	0
Forest__Signincrease	-36.61	5.38	-6.8	0
Dryness	2.48	2.69	0.92	0.36
log10(Area__km2)	-3.03	1.67	-1.81	0.07

The results of this model (Equation (6)) clearly indicate a reduction in the effect of forest cover change with Area (km^2) (Table 6). In fact, the results suggests that for every additional 10 km^2 in catchment size the mean change in flow reduces by 3.5%. Another interesting fact to note is that with the inclusion of Area (km^2) as a variable in the model, the effect of Dryness becomes more significant, possibly suggesting an interaction between Dryness and Area. Including this interaction suggest that the interaction term (log10(Area) by

Dryness) would be significant, but this replaces the effect of Area (results not shown).

The results of this model (Equation (6)) indicate there is at least some evidence ($p = 0.07$) that there is a reduction in the effect of forest cover change on streamflow related to Area (km^2) (Table 6). In fact, the results suggests that for every additional 10 km^2 in catchment size the mean change in flow reduces by 3%. Another interesting fact to note is that with the inclusion of Area (km^2) as a variable in the model, the effect of Dryness becomes slightly more important, possibly suggesting an interaction between Dryness and Area. Including this interaction in the model (Table 7) results in the increased evidence ($p = 0$) that Dryness affects the change in flow caused by changes in forest cover and that the effect of Area is only important ($p = 0.95$)) as an interaction with Dryness.

Table 7: Results of the model including an interaction between Area and the dryness index

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	11.95	7.43	1.61	0.11
DeltaF__perc__pos	0.29	0.1	2.85	0
Forest__Signincrease	-34.62	5.46	-6.34	0
Dryness	5.46	3.1	1.76	0.08
log10(Area__km2)	0.15	2.35	0.06	0.95
Dryness:log10(Area__km2)	-2.62	1.37	-1.91	0.06

4.2. Are some of the variables possibly non-linear?

The work by Filoso et al. (2017) and earlier by Jackson et al. (2005) has indicated that the length of the study might influence the response. This links to the idea from Kuczera (1987) that the effect of logging or deforestation or reforestation reduces with the length of time post intervention (see also Jackson et al. (2005)). In addition to adding *length* (being the difference between the reported start date and end date of data collection in the specific study) as a variable, three other continuous variables (*Dryness, Area, From*) were considered non-linear in this model. As a result a shrinkage smoothing spline (Wood, 2006) was applied to these variables. *From* represents the starting date of the data collection.

$$\Delta Qf\% \sim \Delta\% forest\ cover_{positive} + sign_{forest\ cover} +$$

$$s(log10(Area\ (km^2)) + s(length) + s(Dryness) + \quad (7)$$

$$s(From) + \varepsilon \quad (8)$$

Table 8: Statistical summary for the linear terms in the model with non-linear terms

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	13.99	5.68	2.46	0.01
DeltaF__perc__pos	0.33	0.1	3.51	0
Forest__Signincrease	-37.18	5.48	-6.78	0

Table 9: Statistical summary for the smooth terms in the model with non-linear terms

	edf	Ref.df	F	p-value
s(log10(Area__km2))	0.68	9	0.28	0.05
s(Dryness)	4.28	9	0.94	0.07
s(length)	0	9	0	0.55
s(From)	4.62	9	0.9	0.1

Including non-linearity (Equation (8)) increases the overall explaining power of the model to an adjusted r^2 of 0.26 and deviance explained of 0.29, but creates a few changes in the significance of the variables (Table 9). For example, the smoothed variable for Area (km^2) (p = 4.62)) and Dryness (p = 9))still provides reasonable explanation of changes in stream flow. However *length* does not explain any of the variation. In contrast, *From*, which indicates the start date of the study (and therefore the age of the study) has an effect (p = 0.1)). However, it also increases the chance of over fitting, as the smoothing splines allow significant flexibility, which will be investigated later. Including interactions into the smooths is possible, but the results are even more difficult to interpret given the high flexibility of the two-dimensional smooth.

We now also include the remaining categorical variables (Precipitation data type, Assessment technique, Forest type and Hydrological regime) i.e. Equation (2).

Table 10: Statistical summary for the linear terms the full model

Table 11: Statistical summary for the smooth terms for the full model

	edf	Ref.df	F	p-value
s(log10(Area_km2))	0	9	0	0.37
s(Dryness)	3.96	9	1.68	0
s(length)	0	9	0	0.36
s(From)	8.8	9	3.64	0

This model explains more of the variance, but the improvement is marginal compared to the previous model with a adjusted r^2 of 0.34. This indicates that the categorical variables explain a limited amount of the variance. However, interesting to note from Table 10 that several of the assessment methods are significant. In particular Paired Watersheds experiments (PWE), Hydrological modelling (HM) and Statistical techniques (SH) are strongly significant ($p < 0.05$). In this case, *Area (km^2)* is no longer a significant predictor, the reasons for this will be discussed later.

Figure 5 highlights that the relationship between *log10(Area km^2)* and the change in flow is essentially linear, not significant, and does not need to be smoothed (this is the reason why using penalized smooths following Wood (2006) is useful). It still has a negative slope, indicating that in larger catchments the impact of changes in forest cover on streamflow is less than for smaller catchments. Similarly, the *length* variable is not significant. However, both *From* and *Dryness* variables show strong non-linearity, but this does not show a clear trend due to the scatter and the distributions of the data. For example, in the case of *From* the relationship is clearly strongly influenced by the two data points before 1920. Similarly, *length* and *Dryness* have points with high leverage.

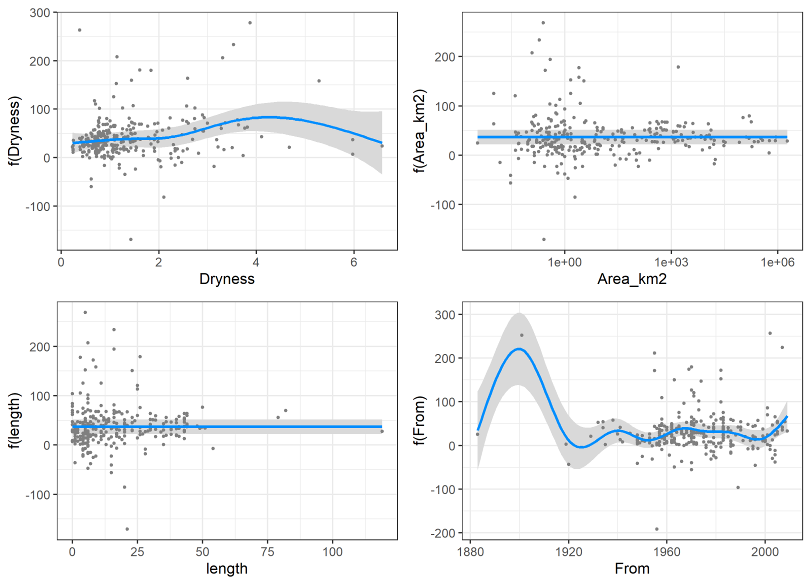

Figure 5: Visualisation of the smooth variables in the model

Table 12: Statistical summary of the smooth terms reducing dataset to studies with the study length shorter than 60 years, Dryness > 4 and studies commencing after 1920

	edf	Ref.df	F	p-value
s(Dryness)	3.21	9	3.22	0
s(log10(Area_km2))	0.46	9	0.11	0.13
s(length)	0	9	0	0.44
s(From)	4.06	9	1.12	0.05

The flexible nature of the splines means that the length variable captures some substantial variation in the data, but it is unclear what exactly is captured. The shape of the conditional response (Figure 5) also does not reflect the type of response highlighted in Filoso et al. (2017) and Jackson et al. (2005). One reason could be the few data points with very long data series, and very old studies (before 1920 essentially), and highly variable responses (Figure 5). Therefore it can be important to investigate what removing these factors has on the overall model and the significance of the variables. The next model therefore removes the following data: *Dryness* > 4, *length* > 60 years, *From* > 1920. This result in a reduction of the data set from 330 to 304 catchments. The model has more explaining power with an adjusted r^2 of 0.34. This results in Dryness now shows a clear non-linear response with drier catchments having a greater impact of changes in forest cover on streamflow (Figure 6). However the other 3 variables are no longer significant due to the scatter in the data, but *length* and *From* show some strong local non-linear behaviour.

5. Discussion

5.1. Catchment size

Essentially, the analysis shows that there is no clear effect of catchment size (Figure 6), and, in contrast to Zhang et al. (2017), there is no evidence a distinct threshold in the size of the catchment that influences the change in the streamflow as a result of changes in forestry. If anything the scatter in the data (in the change in flow) is greater for the smaller catchments then for the larger

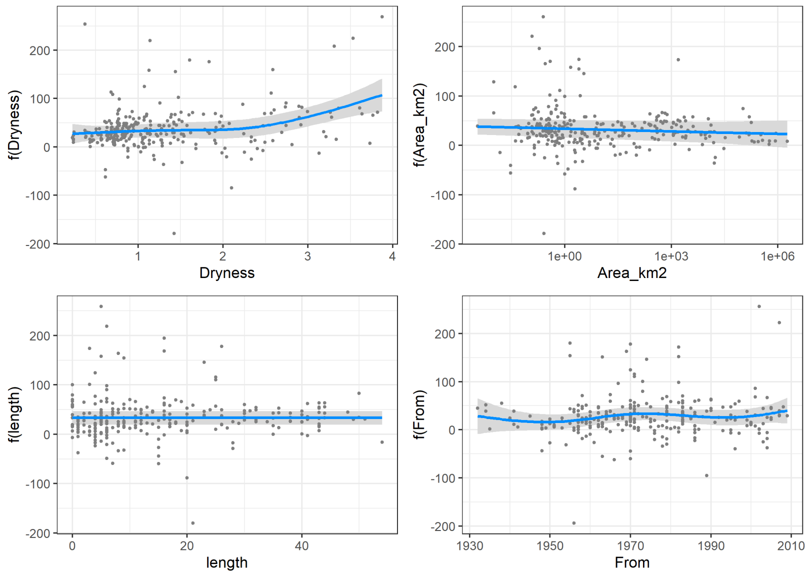

Figure 6: Visualisation of the smooth variables in the model wiht reduced data for dryness and length

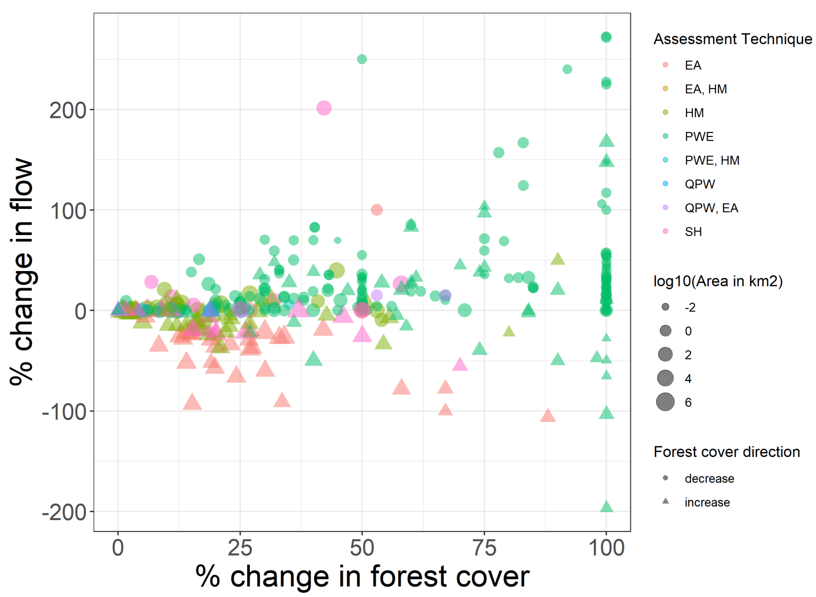

Figure 7: Overview of the data highlighting the dominance of small catchment studies which are fully forested or cleared and the scatter in the data

every 10 km^2 increase in catchment size on the average the recorded forest cover change is approximately 10% lower. This is basically a result of the fact that large changes in forest cover in larger catchments are difficult to "implement" in an experiment.

This is also reflected in the second caveat most of the smaller catchments are "real observed data" using paired watershed studies, while for larger catchments, the analysis are mostly based on modelling approximations using either elasticity analysis (EA), Hydrological modelling (HM) or a combined use of statistical methods (SH) or quasi paired watershed analysis (QPW) (Figure 7). For larger catchments, these techniques all provide an approximation of the effect of forestry on streamflow rather than a direct comparison of catchments. This is a confounding factor that is not easily addressed in the regression modelling attempted here. Furthermore, the catchments analysed using EA, are concentrated in the drier end of the Dryness index scale compared to the other methods, with only the paired watershed experiment (PWE) assessment technique covering the full range of dryness indices.

In other words, the current data sets cannot resolve whether there actually is a non-linear catchment size $\times$ forest cover effect, which then feeds into the buffering in larger catchments.

Apart from a difficulty of analysing complex confounding factors in the data, a general limitation of the type of analysis presented is that this work does not consider the spatial arrangement of the forest clearing in the catchments. While for fully or almost fully cleared smaller catchments this might not be an issue, it is perceivable that for larger catchments being partially cleared, a interaction between spatial location and clearing could be a factor in determining the change in streamflow. Clearing head water catchments on shallower soils might have a larger impact than clearing in downstream areas on deeper soils.

5.2. Model residuals

As pointed out earlier the residuals of the model diverge from the normal distribution for large positive and large negative residuals. These residuals are mainly associated with the small catchments from the paired watershed studies (Figure 7), which show very high variability. The final model removing the data with large values of Dryness and long study lengths has removed some of the spreading, mainly for the large negative residuals (Figure 8).

The reason why the regression model is better able to resolve the variance in the data for the negative residuals (generally related to increases in forest cover) compared the large positive residuals might link back to the issue of buffering and flow paths in the catchments. Small catchments that are stripped of most of the forest cover would provide little buffering, interception and infiltration, does leading to greater changes in flow. In contrast, revegetated catchments would have increased interception and buffering and therefore relatively smaller changes in flow. This also provides an explanation for the differences between forest cover removal and forest cover restoration (Figure 2).

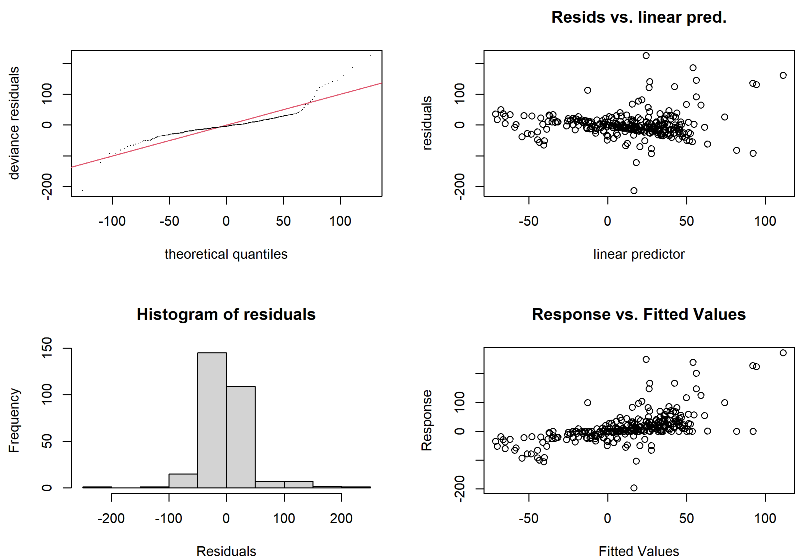

Figure 8: Residual plots for the final model indicating a small improvement in the residual distribution towards normal

5.3. The effect of assessment techniques with very small numbers of observations

Table 13: Distribution of assessment techniques in the data set

Assessment_technique	n
PWE	183
HM	57
SH	43
EA	34
QPW	7
QPW, EA	4
EA, HM	1
PWE, HM	1

One concern is that there are a few assessment techniques in the original dataset with a very low number of observations and this might skew the results of the analysis. This includes the category of Quasi paired watersheds and combinations of elasticity analysis and hydrological modelling (EA,HM) and paired watersheds and hydrological modelling (PWE,HM) (Table 13 and Figure 9).

Table 14: Statistical overview of the linear components of the model removing studies with limited observations in the assessment techniques

	Estimate	Std. Error	t value	Pr(>|t|)
(Intercept)	-27.03	18.34	-1.47	0.14
DeltaF_perc_pos	0.29	0.1	2.96	0
Forest_Signincrease	-22.23	6.83	-3.25	0
Precip_data_typeOB	-11.91	13.85	-0.86	0.39
Precip_data_typeSG	18.07	15.65	1.15	0.25
Assessment_techniqueHM	36.48	12.3	2.97	0
Assessment_techniquePWE	56.52	12.33	4.58	0

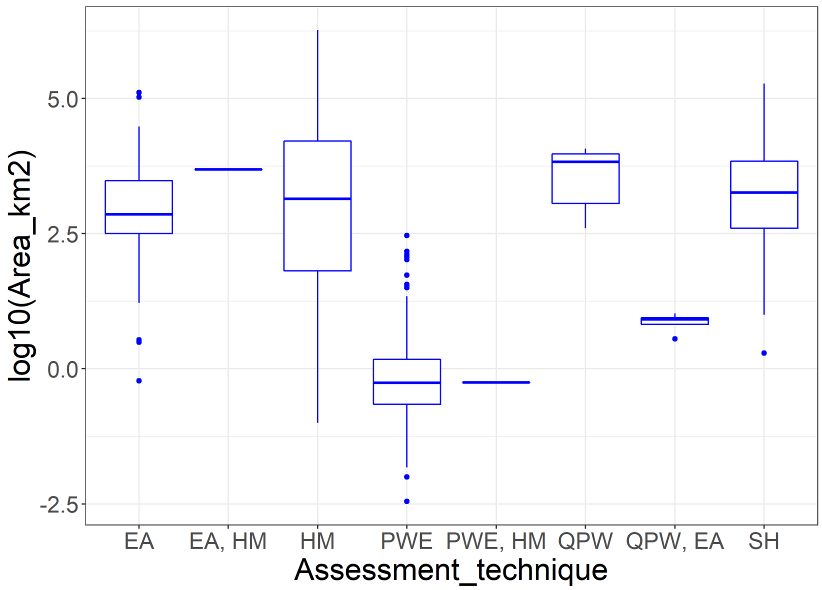

Figure 9: Boxplot of the log base 10 of the catchment area (in km2) for the different assessment techniques, showing the dominance of small catchments in the paired watershed experiments

Table 15: Statistical overview of the smooth components of the model removing studies with limited observations in the assessment techniques

	edf	Ref.df	F	p-value
s(Dryness)	2.93	9	2.41	0
s(log10(Area_km2))	0.45	9	0.1	0.14
s(length)	0	9	0	0.4
s(From)	3.84	9	0.66	0.17

Concentrating only on the assessment techniques that have more than 10 observations in the data set does not change much in the results (Table 14 and 15). It strengthens the significance of the different assessment techniques and *Dryness* but generally results in the same interpretation. Overall this suggests that although those observations have some impact on the overall relationships, they do not strongly bias the outcomes.

However, the model results also clearly highlight that some of the assessment techniques (in particular paired watershed studies (PWE) and combined use of statistical methods and hydrographs (SH)), have a strong impact on the predicted change in flow. Particularly, relative to EA (elasticity approaches) all other assessment techniques have higher predicted changes in flow. In other words, there is a distinct difference in the way the change in flow is assessed, and the EA method (for example in Zhou et al. (2015)) appears to suggest a much smaller effect on the change in flow. However, as indicated earlier, the EA studies are all on the drier end of the *Dryness* spectrum, highlighting another unresolved interaction in the data.

5.4. The effect of climate

In drier catchments, changes in forest cover have greater impact on flow, which is similar to the observations in earlier studies (Filoso et al., 2017; Zhang et al., 2017; Zhou et al., 2015). This is most likely because in these catchments the overall flow is surface flow dominated and therefore the buffering that is afforded by the groundwater inputs is not as great. As the dataset currently does not include a separate variable for groundwater inputs (although this effect is estimated in several of the studies), the effect again cannot be analysed separately.

Excluding the few catchments that have very high dryness values, clarified the *Dryness* trend, agreeing with earlier studies and showing a increase in the change in flow for drier catchments. However, this really only starts to have an effect for Dryness > 2.

5.5. Interactions

Generally this study did not consider interactions, but the above discussion suggest that there are possible several interactions. The relationships between forest cover change and *Area (km^2)* and between *Area (km^2)* and assessment technique have already been highlighted. However there are further unexplored interactions between the study length and some of the variables and *From* and the other variables.

A principle component analysis of the numeric data reveals some of these interactions (Figure 10), such as between *length* and *Dryness* and between *From* and *Area (km^2)*. Including these interactions into the smooths of the models (data not shown) increases the explained variance slightly but does not fundamentally change the significance of the different variables.

5.6. Further considerations

In contrast to Filoso et al. (2017), we did not identify the length of the observation period as a significant variable in our final model. There are further confounding factors in the data, which were also classified by Filoso et al. (2017) and these might create biases in the data set that can impact the overall assessment. For example, snow dominated hydrological regimes (SD), are dominated by Coniferous Forests (CF), while the majority of the rain dominated regimes are all broadleaf of mixed type forests (BF or MF). However, the forest type classification is very coarse and does not fully capture possible physiological differences that could affect evapotranspiration and therefore changes in streamflow (Vervoort et al., 2021). This is not further investigated in this study, but with more data available this might provide further opportunities for investigations.

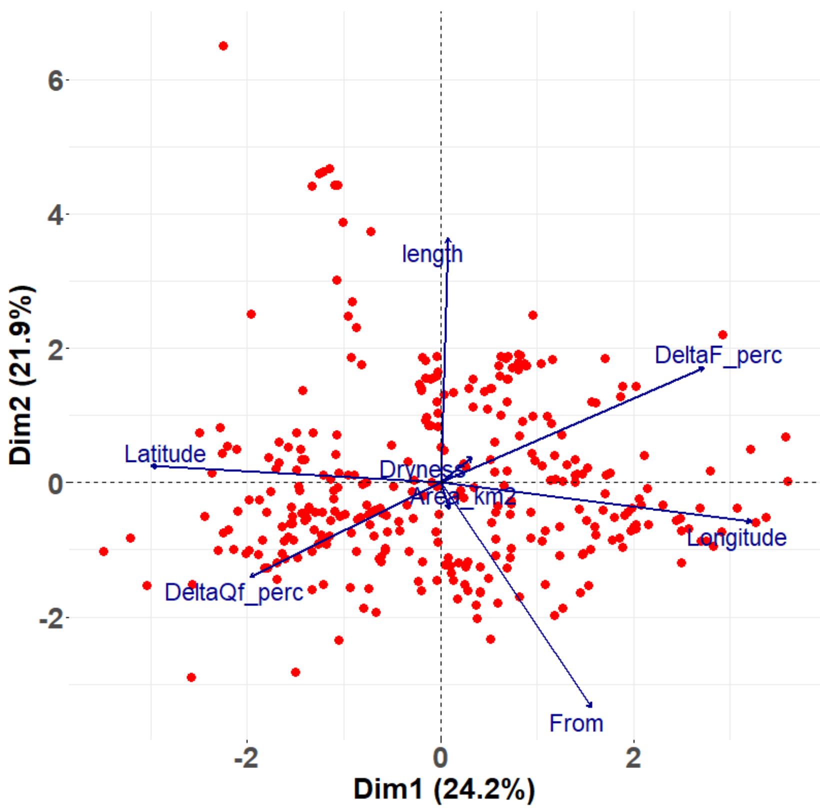

Figure 10: Biplot of the first two principle components using a principle component analysis on the numerical values of the

By making the updated the database of this study available, we hope that this provides further incentive to investigate the impact of land cover change on streamflow more generally.

6. Conclusions

More rigorous checking of data and statistical analysis results in both agreement and disagreement with older studies. It demonstrates that analysis of large databases of essentially "aggregated data" should be considered carefully.

Results of this statistical analysis need to be considered "conditional on the data" Conditional on the data, the impact of forestry on streamflow is:

- Greater for forest clearing then for reforestation
- Possibly reduced for larger watersheds, but this is only in interaction with other factors such as climate
- Increases for drier watersheds
- Sensitive to the assessment method used in the historical data

Stronger statements about the trends in the change in flow cannot be made until more data or better data becomes available in this area. Furthermore, the current study analyses a large global dataset. This analysis does not exclude more local and regional effects that cannot be identified in the global data.
