There has been an long and on-going discussion in the hydrological literature around the impact of forests on streamflow (Andréassian, 2004; Brown et al., 2013, 2005; Filoso et al., 2017; Jackson et al., 2005; Zhang et al., 2017). The historic work highlights a general consensus that if forest areas increase, streamflow decreases and vice-versa. The most dramatic result in relation to this, is Figure 5 in Zhang et al. (2011) indicating (for Australian watersheds) a 100% decrease in stream flow for watersheds with 100% forest cover. However, on the other end of the spectrum, in a series of French watersheds (Cosandey et al., 2005), there was no change in streamflow characteristics in 2 of the three watersheds studied in relation to deforestation.

Several review papers have summarized different studies across the globe, in relation to paired watershed studies (Bosch and Hewlett, 1982; Brown et al., 2005), related to reforestation in particular (Filoso et al., 2017), and more generally (Jackson et al., 2005; Zhang et al., 2017). These studies aim to generalize the individual findings and to identify if there are global trends or relationships that can be developed. The most recent reviews (Filoso et al., 2017; Zhang et al., 2017) developed an impressive global database of watershed studies in relation to changes in streamflow due to changes in forest cover. The Zhang et al. (2017) dataset, which covers over 250 studies, is described in terms of the change in streamflow as a result of the change in forest cover, where studies related to both forestation (increase in forest cover) and deforestation (decrease in forest cover) were included. In contrast, the paper by Filoso et al. (2017) focused primarily on reforestation, and covered an equally impressive database of 167 studies using a systematic review. In this case the collected data is mostly coded as count data and only a subset of 37 studies was analysed for actual water yield change.

Preferresconding Authornal of Hydrology
**Equal contribution

The conclusions of the first paper (Zhang et al., 2017) suggest that there is a distinct difference in the change in flow as a result of forestation or deforestation between small watersheds, defined as $< 1000 \; \mathrm{km^2}$ and large watersheds $> 1000 \; \mathrm{km^2}$. While for small watersheds there was no real change in runoff with changes in cover, for large watersheds there was a clear trend showing a decrease in runoff with and increase in forest cover. Their main conclusion was that the response in annual runoff to forest cover was scale dependent and appeared to be more sensitive to forest cover change in water limited watersheds relative to energy limited watershed (Zhang et al., 2017).

The second study (Filoso et al., 2017) was a systematic review which classified the historical research and highlighted gaps in the spatial distribution, the types of studies and the types of analysis. Their main conclusion was also that reforestation decreases streamflow, but that there were many interacting factors. For a subset of quantitative data (37) they showed a relationship between catchment size and decline in streamflow.

A final summary paper that includes much of the same data as Zhang et al. (2017) and Filoso et al. (2017) is Zhou et al. (2015), which has one author in common with Zhang et al. (2017). However, this paper aims to explain the variation in the data using the Fuh model, and in particular aims to link the variation in the observed data to variations in the exponent m in the model. A key observation is that in drier environments, the effects of deforestation are much greater than in wetter environments, which is also suggested by Figure 4 in Zhang et al. (2017).

Encouraged by the work presented by Zhang et al. (2017) and Filoso et al. (2017) and the fantastic database of studies presented by these authors, we believe we can add to the discussion. In this paper, the aim is to develop further analysis of the collected data and expanding and combining the two data sets to provide further depth.

In particular, the main method in the work by Zhang et al. (2017) is using simple linear regression, and in Filoso et al. (2017) the focus is mainly on classification. As Zhang et al. (2017) points out, the main assumption in their work is that the threshold at 1000 km² is a distinct separation between "small" and "large" watersheds, but the subset of data in Filoso et al. (2017) does not appear to support this. And while te work Filoso et al. (2017) provides important insights in study types, analysis types and broad classification, there is limited quantification of actual impact. This is because the work had a strict criterion to select quantitative studies. However, given the fantastic data sets collected, the analyses can be easily expanded to look at interactions between the terms and to test the assumption of a distinct threshold at 1000 km².

As a result the objective of this paper is to 1) enhance the data set from Zhang et al. (2017) with further watersheds (such as from Filoso et al. (2017)) and spatial coordinates and 2) to analyse the possibility of non-linear, interactions and partial effects of the different factors and variables in the data using generalised linear (GLM) and generalised additive models (GAM Wood (2006)).

Building on the analyses by Zhang et al. (2017) and Filoso et al. (2017), and combining their conclusions, the main hypothesis to test is that the change

in streamflow is impacted by the change in forest cover. However, this change is clearly modulated by the area under consideration (affecting the length of the flowpaths Zhou et al. (2015)), the length of the study (c.f. Jackson et al. (2005)) and possibly the climate (as indicated by either E0/Pa or latitude and longitude Filoso et al. (2017); Zhou et al. (2015)).

However, there could be further confounding factors, which are eluded to by Filoso et al. (2017):

- the type of analysis, i.e. paired catchment studies, modelling, time series analysis etc.
- the age of the study, assuming that historical studies might not have had the ability to measure at the accuracy that currently is available to researchers, or that more careful historical attention to detail in field studies might have been lost more recently due to reductions in research investment.

Finally, this work aims to point to further research that can expand this area of work, based on the collected data, to better understand the impact of forest cover change on streamflow.

The original data sets

The starting point of this paper is the data base of studies which were included in Zhang et al. (2017) as supplementary material. The columns in this data set are the watershed number, the watershed name, the Area in km², the annual average precipitation (Pa) in mm, the forest type, hydrological regime, and climate type, the change in forest cover in % (Δ F%) and the change in streamflow in % (Δ Qf(%), based on equation 1 in Zhang et al. (2017)), the precipitation data type, the assessment technique, and the source of the info, which is a citation. Several of these columns contain abbreviations to describe the different variables, which are summarised in Table 1.

Table 1 Summary of abbreviations of factors used in the Zhang et al. (2017) data set

Factor	Abbreviation	Definition
forest type	CF	coniferous forest
	BF	broadleaf forest
	MF	mixed forest
hydrological regime	RD	rain dominated
	SD	snow dominated
climate type	EL	energy limited
	WL	water limited
	EQ	equitant

Factor	Abbreviation	Definition
precipitation data type	OB SG MD	observed spatial gridded modelled
assessment technique	PWE QPW HM EA SH	paired watershed experiment quasi-paired watershed experiment hydrological modelling elasticity analysis combined use of statistical methods and hydrographs

While Zhang et al. (2017) use the dryness index in their analysis, potential or reference evapotranspiration was not originally included as part of the published data set. We combined the tables for small ($< 1000 \text{ km}^2$) and large ($>= 1000 \text{ km}^2$) watershed data sets in our analysis.

Additional data collection

To enhance the existing data set, this study added additional variables and cross-checked the studies with the data set from Filoso et al. (2017). In particular, we focussed on the 37 data points included in the quantitative analysis in Filoso et al. (2017).

In addition, additional variables added were the latitude and longitude for the center of the watershed as an approximation of its spatial location. Using this information annual average reference evapotranspiration (E0) was extracted from **XXXXX** if a value of E0 was not available from the original papers. For large watersheds, this value, similar to annual average rainfall, is only an approximation of the climate at the location.

The length of the study can be a variable influencing the change in flow (e.g. Jackson et al., 2005) and therefore, the length, starting data and completion date of the different studies was extracted from the references provided by Zhang et al. (2017).

Several additional data points from watershed studies were extracted from Zhang et al. (2011), Zhao et al. (2010), Borg et al. (1988), Thornton et al. (2007), Zhou et al. (2010), Rodriguez et al. (2010), Ruprecht et al. (1991) and Peña-Arancibia et al. (2012), and these were checked against the existing studies to prevent overlap. In the citation column in the data set, in general the main reference for the calculated change in streamflow was used, because sometimes the original study did not provide the quantification of the change in streamflow (i.e. Table 6 in Zhang et al. (2011))

The final column in the improved data set is a "notes" column, which is not further used in the analysis, but gives context to some of the data for future research and highlights some of the discrepancies that we found between the original papers and the data in the tables from Zhang et al. (2017).

Statistical modelling

Warning: NAs introduced by coercion

Warning: NAs introduced by coercion

To estimate how the change in streamflow is affected by the change in forest cover while considering the effects of the other variables, we applied generalised additive modelling (GAM) (Wood, 2006).

The first model applied in this analysis is based on the main hypothesis outlined above, can the change in streamflow be predicted from the change in forest cover, modulated by area, the length of the study and the climate.

$$\Delta\%Q \sim \Delta\% forest + Pa + Area + Latitude + Longitude + \varepsilon$$
 (1)

However, the overall skewed distribution of the predictant $(\Delta\%Q)$ is problematic, and this results in a skewed distribution of the GAM model residuals, which violates the linear model assumptions. As a result we transformed $\Delta\%Q$ back to fractions (0 - 1) and log transformed using log10(x + 1), where x is ΔQ . After transformation the model residuals approximate $\sim N(0, \sigma^2)$ and this results in the following equation:

$$log10(\frac{\Delta\%Q}{100} + 1) \sim \Delta\%forest\ cover + Pa + Area + Latitude + Longitude + \varepsilon$$

$$(2)$$

A second model included all the variables in the analysis from Zhang et al. (2017) in one model:

$$log10(\frac{\Delta\%Q}{100} + 1) \sim \Delta\% forest\ cover + s(Pa, k = 3) + s(Area, k = 3) + forest\ type + climate\ type + assessment\ type + hydrologic\ regime + \varepsilon$$
 (3)

In this model, no direct interactions are assumed, and the assumption is that all continuous variables (such as Pa) can have a linear or non-linear relationship with $log10(\Delta Q)$. This means that a smooth function s() is applied to the variable. To restrict the smoothness of the fit, the smoothness factor k is restricted to a value of 3 (Wood, 2006). This restriction was applied to smooth variables throughout this paper and we have dropped this from the notation in subsequent equations.

For the model in equation 3, we only used the data from Zhang et al. (2017) to make sure that the additional watersheds added to the data set did not influence the analysis. Given that in Zhang et al. (2017), dryness $(\frac{E0}{Pa})$ is used to look at variations in the change in flow, we also fitted the following model:

$$log10(\frac{\Delta\%Q}{100} + 1) \sim \Delta\%forest\ cover + s(\frac{E0}{Pa}) + s(Area) + forest\ type +$$

$$climate\ type + assessment\ type +$$

$$hydrologic\ regime + \varepsilon$$

$$(4)$$

Subsequently, using the full data set, including the additional watersheds and the additional variables the following two models were fitted:

$$log10(\frac{\Delta\%Q}{100} + 1) \sim \Delta\%forest\ cover + s(Pa) + s(Area) + s(Latitude) + s(Longitude) + s(begin_{year}) + s(length_{study}) + forest\ type + climate\ type + assessment\ type + hydrologic\ regime + \varepsilon$$
 (5)

$$log10(\frac{\Delta\%Q}{100} + 1) \sim \Delta\%forest\ cover + s(\frac{E0}{Pa}) + s(Area) + s(Latitude) + s(Longitude) + s(begin_{year}) + s(length_{study}) + forest\ type + climate\ type + assessment\ type + hydrologic\ regime + \varepsilon$$
 (6)
